#### Abstract

A path coloring of a graph G is a vertex coloring of G such that each color class induces a disjoint union of paths. We present two efficient algorithms to construct a path coloring of a plane graph.

The first algorithm, based on a proof of Poh, is given a plane graph; it produces a path coloring of the given graph using three colors.

The second algorithm, based on similar proofs by Hartman and Škrekovski, performs a list-coloring generalization of the above. The algorithm is given a plane graph and an assignment of lists of three colors to each vertex; it produces a path coloring of the given graph in which each vertex receives a color from its list.

Implementations of both algorithms are available.

## 1 Introduction

All graphs will be finite, simple, and undirected. See West [10] for graph theoretic terms. A path coloring of a graph G is a vertex coloring (not necessarily proper) of G such that each color class induces a disjoint union of paths. A graph G is path k-colorable if G admits a path coloring using k colors.

Broere & Mynhardt conjectured [2, Conj. 16] that every planar graph is path 3-colorable. This was proven independently by Poh [8, Thm. 2] and by Goddard [6, Thm. 1].

**Theorem 1.1** (Poh 1990, Goddard 1991). If G is a planar graph, then G is path 3-colorable.  $\square$ 

It is easily shown that the "3" in Theorem 1.1 is best possible. In particular, Chartrand & Kronk [5, Section 3] gave an example of a planar graph whose vertex set cannot be partitioned into two subsets, each inducing a forest.

Hartman [7, Thm. 4.1] proved a list-coloring generalization of Theorem 1.1 (see also Chappell & Hartman [4, Thm. 2.1]). A graph G is  $path\ k$ -choosable if, whenever each vertex of G is assigned a list of k colors, there exists a path coloring of G in which each vertex receives a color from its list.

**Theorem 1.2** (Hartman 1997). If G is a planar graph, then G is path 3-choosable.  $\Box$ 

Essentially the same technique was used by Škrekovski [9, Thm. 2.2b] to prove a result slightly weaker than Theorem 1.2.

We discuss two efficient path-coloring algorithms based on proofs of the above theorems. We distinguish between a *planar* graph—one that can be drawn in the plane without crossing edges—and a *plane* graph—a graph with a given embedding in the plane.

In Section 2 we outline our graph representations and the basis for our computations of time complexity.

Section 3 covers an algorithm based on Poh's proof of Theorem 1.1. The algorithm is given a plane graph; it produces a path coloring of the given graph using three colors.

Section 4 covers an algorithm based Hartman's proof of Theorem 1.2, along with the proof of Škrekovski mentioned above. The algorithm is given a plane graph and an assignment of a list of three colors to each vertex; it produces a path coloring of the given graph in which each vertex receives a color from its list.

Implementations of both algorithms are available; see Bross [3].

# 2 Graph Representations and Time Complexity

We will represent a graph via adjacency lists: a list, for each vertex v, of the neighbors of v. A vertex can be represented by an integer  $0 \dots n-1$ , where n is the order of the graph.

A plane graph will be specified via a rotation scheme: a circular ordering, for each vertex v, of the edges incident with v, in the order they appear around v in the plane embedding; this completely specifies the combinatorial embedding of the graph. Rotation schemes are convenient when we represent a graph using adjacency lists; we simply order the adjacency list for each vertex v in clockwise order around v; no additional data structures are required.

We will assume an integer RAM model of computation. The input for each algorithm will be a triangulated plane graph with n vertices and m edges, represented via adjacency

lists. The input size will be n, the number of vertices. Note that  $\mathcal{O}(m) = \mathcal{O}(n)$ , so it is equivalen to take the input size to be m, the number of edges. Moreover, arbitrary simple planar graphs may be plane embedded and triangulated in  $\mathcal{O}(n)$  time, see [1].

In Section 4, given an edge uv, we will need an efficient operation to find v's entry in u's adjacency list from u's entry in v's list. An augmented adjacency list is an adjacency list such that for any edge uv, a reference to v's entry in u's list is stored in u's entry in v's list, and vice versa. Given an adjacency list representation of a graph, an augmented adjacency list representation may be constructed in  $\mathcal{O}(m)$  time via the following procedure.

### Implementation 2.1.

**Input:** An adjacency list representation Adj of a graph G.

**Output:** An augmented adjacency list representation Adj of G with the same rotation scheme as Adj.

**Step 1:** Construct an augmented adjacency list copy Adj' of Adj with the reference portion of each entry uninitialized.

**Step 2:** For each vertex v construct an array  $\operatorname{Wrk}[v]$  storing vertex-reference pairs. For each v from 0 to n-1 iterate through  $\operatorname{Adj'}[v]$ . For each neighbor u in  $\operatorname{Adj'}[v]$  append the pair  $(v, r_v(u))$  to  $\operatorname{Wrk}[u]$  where  $r_v(u)$  is a reference to u's entry in  $\operatorname{Adj'}[v]$ .

**Step 3:** For each v from n-1 to 0 iterate through  $\operatorname{Wrk}[v]$ . At the pair  $(u, r_u(v))$  in  $\operatorname{Wrk}[v]$  the last element of  $\operatorname{Wrk}[u]$  will be  $(v, r_v(u))$ ; for details on why this is, see below. Use  $r_u(v)$  and  $r_v(u)$  to look up and assign references for the edge uv in  $\operatorname{Adj'}[u]$  and  $\operatorname{Adj'}[v]$ . Remove  $(v, r_v(u))$  from the back of  $\operatorname{Wrk}[u]$ .

After completing Step 2 in Algorithm 2.1 the array Wrk[v] contains a pair  $(u, r_u(v))$  for each neighbor of v, sorted in increasing order of by the neighbor u.

At a given iteration of Step 3 in Algorithm 2.1 let v be the current vertex. For each edge  $uw \in E(G)$  such that u < w and v < w, prior iterations of Step 3 will have initialized the references for uw in Adj'[u] and Adj'[w], and also removed the pair  $(w, r_w(u))$  from Wrk[u]. The current iteration will handle all edges  $uv \in E(G)$  with v > u.

# 3 Path Coloring: the Poh Algorithm

We will first describe Poh's algorithm for path 3-coloring plane graphs.

#### **Algorithm 3.1** (Poh 1990).

**Input:** A weakly triangulated plane graph G with outer face a cycle  $C = v_1, v_2, \ldots, v_k$  and a 2-coloring of C such that each color class induces a path,  $P_1 = v_1, v_2, \ldots, v_l$  and  $P_2 = v_{l+1}, v_{l+2}, \ldots, v_k$  respectively.

**Output:** An extension of the 2-coloring of C to a path 3-coloring of G such that no vertex in G - C receives the same color as a neighbor of that vertex in C.

**Step 1:** If G = C then G is already path 3-colored and we are done. Otherwise there are two cases to consider.

Case 1.1: Suppose C is an induced subgraph of G. Let  $u, w \in V(G) - V(C)$  such that the cycles  $u, v_1, v_k$  and  $w, v_l, v_{l+1}$  each exist and are faces of G; note that u and w are

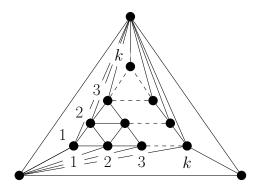

Figure 1: The collection of graphs  $\{G_k\}_{k\in\mathbb{N}}$  on which Poh performs poorly.

unique, but may not be distinct. Since C is induced and  $G \neq C$ , G - C is connected. Let  $P_3 = u_1, u_2, \ldots, u_r$  be a shortest u, w-path in G - C. Color each vertex of  $P_3$  with the third color not used in the 2-coloring of C. Let  $C_1 = v_1, v_2, \ldots, v_l, u_r, u_{r-1}, \ldots, u_1$  and  $C_2 = u_1, u_2, \ldots, u_r, v_{l+1}, v_{l+2}, \ldots, v_k$ .

Case 1.2: Suppose C is not an induced subgraph. Then there exists an edge  $v_i v_j \in E(G) - E(C)$  such that  $i \leq l < j$ . Let  $C_1 = v_1, v_2, \ldots, v_i, v_j, v_{j+1}, \ldots, v_k$  and  $C_2 = v_i, v_{i+1}, \ldots, v_j$ .

**Step 2:** Apply Algorithm 3.1 separately to the subgraph bounded by  $C_1$  and the subgraph bounded by  $C_2$ .

Note that the graph G is finite and the recursive step applies the algorithm to two proper subgraphs of G. Therefore Algorithm 3.1 must terminate.

Let G be a triangulated plane graph. We may trivially path 2-color the outer triangle. Applying Poh's algorithm extends this coloring to a path 3-coloring of G.

A natural way to implement Poh's algorithm is to use a breadth-first search to construct the shortest path in Case 1.1. However, this method unfortunately results in an algorithm that is not linear. To see this consider the family of graphs  $\{G_k\}_{k\in\mathbb{N}}$  depicted in Figure 1. Fix  $k\in\mathbb{N}$  and note that  $n=n(G_k)=k(k+1)/2+3$ . Assume that the outer triangle 2-colored such that the top vertex assigned a color distinct from the bottom two. At iteration i of Poh's algorithm, the shortest path through the interior will be the path of length l=k-i+1 directly along the base of the inner triangle. A breadth-first search of this inner triangle will hit all (l)(l+1)/2 vertices in order to find this path. Therefore the total number of operations performed will be

$$\Theta\left(\sum_{l=1}^{k} \frac{l(l+1)}{2}\right) = \Theta(n^{3/2}).$$

So Poh's algorithm with breadth-first search is  $\Omega(n^{3/2})$ .

Howeveer, the correctness of Poh's algorithm did not rely on locating the shortest uw-path, only on locating some induced uw-path. Modifying Poh's algorithm to locate induced paths will allow us produce a linear time implementation.

The general strategy will be to walk clockwise along the colored path  $P_1 = v_1, v_2, \ldots, v_l$  in the outer cycle C, marking those vertices interior to C that have a neighbor in  $P_1$ . We will then construct an induced path  $P_3 = u_1, u_2, \ldots, u_d$ , consisting only of marked vertices, such that  $C_1 = P_1 \cup P_3 \cup \{u_1v_1, u_dv_l\}$  is a cycle and all marked vertices are contained in the subgraph of G bounded by  $G_1$ .

If  $C = v_1, v_2, \dots, v_k$  is a cycle, then we will treat vertex indices mod k. That is,  $v_i = v_{i+k}$  for any  $i \in \mathbb{Z}$ .
